

Global Oil Price Crisis Analysis Report

Business analysis report based on the provided CSV dataset, SQL logic, and Power BI dashboard asset

Observation window: 20 Feb 2026 to 25 Apr 2026

Prepared automatically from the client-provided files

Key Highlights

- Brent moved from \$69.4 to a peak of \$127.6.
- WTI moved from \$64.5 to a peak of \$112.5.
- Event-tagged observations represented 24 of 34 rows.
- The average Brent-WTI spread reached \$9.57.
- Price comovement remained extremely high, with correlation 0.9894.

Table of Contents

16. 15. Limitations and Opportunities for Enhancement

Executive Summary

The dataset covers 34 dated observations from 20 Feb 2026 to 25 Apr 2026. Within that period, 24 records are tagged as event days and 10 as normal days. Brent opened at \$69.4 per barrel and finished at \$106.0, while WTI moved from \$64.5 to \$94.0. The observation window therefore captures a market that began from a relatively stable base, experienced a sharp geopolitical shock, and then partially mean-reverted while retaining a meaningful risk premium.

The central business finding is that the event regime structurally lifted the level of both benchmarks. Average Brent price on event days was \$112.71 versus \$82.16 on normal days; average WTI was \$102.43 versus \$74.29. Event days also carried stronger average positive returns for Brent (2.16%) than the non-event period (-0.16%), indicating that the price shock was not simply a one-day outlier but a regime shift in market valuation.

Peak stress was visible in the first shock window. Brent advanced from the pre-event reference level of \$74.5 on 26 Feb 2026 to a local high that was \$35.5 higher during the first week, a jump of 47.65%. The full sample peak reached \$127.6 on 02 Apr 2026. Importantly, the spread between Brent and WTI widened as the crisis evolved, reaching a maximum of \$20.20 on 10 Apr 2026, which implies relative tightness or a larger geopolitical premium embedded in Brent-linked pricing.

Figure: 01 Price Series

1. Scope, Objective, and Business Questions

The objective of the analysis is to turn a compact but information-rich dataset into a business decision document. The dataset records daily benchmark prices, simple daily returns, an event indicator, and corresponding volatility measures. The associated SQL script reveals the intended analytical logic: identify the dimensions of the dataset, isolate event days, compare up and down days, track cumulative returns, evaluate volatility regimes, and tell a crisis story from pre-shock conditions to de-escalation.

From a business perspective, the report answers five practical questions. First, how strongly were benchmark prices repriced during the event window? Second, did Brent and WTI move together or did the shock create segmentation between the two benchmarks? Third, how much additional volatility was embedded in the market during the crisis period? Fourth, did the market normalize after the initial shock, or did a residual premium remain? Fifth, does the Power BI dashboard and SQL design support repeatable executive reporting for future commodity risk monitoring?

This report was prepared from three assets supplied by the client: a cleaned CSV dataset containing Brent and WTI daily prices, returns, event flags, and volatility measures; a SQL script that defines the analytical questions and segmentation logic; and a Power BI dashboard file that packages the same analytical story into visual form. The report therefore combines numerical interpretation, model review, and presentation review in one business-facing document.

2. Source Assets and Analytical Workflow

The cleaned CSV file is the numerical core of the project. It includes the date, Brent and WTI prices, corresponding one-day returns, binary event tagging, and rolling volatility estimates. These fields are sufficient to support both descriptive analysis and a basic event-study framework. The SQL file acts as a structured audit trail of intended calculations, including ranking days by price or return, calculating spreads, classifying volatility, and segmenting the period into crisis phases. The PBIX dashboard represents the presentation layer of the same logic.

The workflow used for this report followed a standard business analytics sequence. Data was first ordered chronologically and checked for field consistency. Derived measures such as the Brent-WTI spread and cumulative return paths were then calculated. The sample was segmented into pre-crisis, shock and escalation, peak crisis, extreme swings, and de-escalation. Results were interpreted in a business context rather than only a statistical context, with attention to pricing pressure, transmission of volatility, and implications for hedging, budgeting, and dashboard governance.

This layered asset set is useful because it demonstrates not only what happened, but how the reporting stack was intended to be used. The SQL captures analytical reasoning, the dataset stores measurable evidence, and the dashboard translates that evidence into an executive consumption format. That alignment is a strength of the project and makes the resulting report more credible for decision support.

Figure: 08 Scatter

3. Dataset Structure and Data Quality Assessment

The dataset contains 34 rows and 8 columns. Although the sample is relatively short, it is dense enough to illustrate a complete market narrative. Coverage begins on 20 Feb 2026 and ends on 25 Apr 2026. The early rows show low-to-moderate price levels, smaller daily return magnitudes, and lower volatility. From 27 Feb 2026 onward, the event flag turns on and the series becomes visibly more unstable, supporting the interpretation that the data was intentionally curated around a stress episode.

From a quality standpoint, the file is well structured. Column names are clear, all numeric fields are usable without extensive cleaning, and the event indicator is encoded consistently as 0 or 1. The dataset does not appear to contain blank rows or malformed observations. However, because the sample is small and focuses on a specific crisis window, it should be treated as an event-study dataset rather than a full historical market database. That distinction matters because conclusions about structural long-term pricing should remain cautious.

One business strength of the file design is that it already contains return and volatility fields. That reduces operational ambiguity in downstream reporting because the dashboard and SQL are not forced to compute those fields repeatedly from raw prices. At the same time, governance documentation should clarify how volatility was

constructed, including the window length and whether it is close-to-close realized volatility or a smoothed estimate. Without that metadata, executive users may trust the number while analysts interpret it differently.

Metric	Value
Observation window	20 Feb 2026 to 25 Apr 2026
Total records	34
Event days	24
Normal days	10
Starting Brent price	\$69.4
Ending Brent price	\$106.0
Peak Brent price	\$127.6 on 02 Apr 2026
Starting WTI price	\$64.5
Ending WTI price	\$94.0
Peak WTI price	\$112.5 on 02 Apr 2026
Average Brent-WTI spread	\$9.57
Maximum spread	\$20.20 on 10 Apr 2026
Brent/WTI price correlation	0.9894
Brent/WTI return correlation	0.9048

2026

4. Baseline Market Conditions Before the Shock

The pre-crisis segment contains 7 observations and represents the calmest part of the sample. During this stage, average Brent was approximately 71.04 and average WTI 65.63. Daily returns were positive but contained, while volatility was materially lower than in the later stress period. The market environment in this phase can be interpreted as a stable benchmark regime with only moderate daily repricing and a relatively narrow inter-benchmark spread.

This baseline matters for business planning because it is the anchor from which the crisis premium can be measured. A buyer, refinery planner, treasury team, or budget owner would typically treat this regime as the operating reference case. Once the event begins, every increase above this baseline should be interpreted not just as a higher spot price, but as a change in procurement cost assumptions, margin sensitivity, and hedge effectiveness. In that sense, the pre-crisis regime functions as the counterfactual that makes the later shock economically meaningful.

The day immediately before the shock, 26 Feb 2026, is especially important. Brent closed at \$74.5, making it the key reference point for measuring the speed and magnitude of the first escalation phase. The next trading day generated the strongest one-day Brent return in the sample: 14.09% on 27 Feb 2026. This shows that the market transition from baseline to crisis was abrupt rather than gradual.

Figure: 10 Event Path

5. Shock Window Analysis: First-Week Escalation

The first week after the event tag activates is the most dramatic segment in the dataset. Brent moved from the pre-event level of \$74.5 to triple-digit territory within days. In absolute terms the initial shock added \$35.5 to Brent from the pre-event reference, equivalent to a 47.65% jump. WTI followed the same direction, confirming that the market viewed the event as a broad oil shock rather than a narrow benchmark-specific anomaly.

The daily return profile during this window shows a mixture of momentum and turbulence. Multiple positive sessions follow one another, but pullbacks appear almost immediately, implying a market where every escalation is reassessed in real time. This pattern is typical of crisis repricing: headline risk creates large directional moves, while uncertainty about duration, supply response, or policy intervention prevents a smooth trend line. For managers, that means spot procurement and hedging decisions become highly timing sensitive.

The first-week shock also likely shaped trader and executive psychology for the remainder of the sample. Once a benchmark can reprice that fast, forward-looking decisions incorporate not only current spot levels but the possibility of another gap move. Risk managers therefore shift focus from average price alone to both convexity and liquidity. The dataset supports this interpretation because volatility measures remain elevated even after the initial leap, showing that uncertainty did not disappear when prices first stabilized above 100.

Figure: 02 Returns

Figure: 07 Cumulative Returns

6. Peak Crisis and Price Discovery

The crisis does not end with the first jump. Instead, the market enters a price-discovery phase in which higher highs continue to appear. Brent ultimately peaks at \$127.6 on 02 Apr 2026, while WTI peaks at \$112.5 on 02 Apr 2026. The persistence of rising highs indicates that the market needed time to establish the full value of the disruption. This is a hallmark of complex commodity shocks: price discovery occurs in layers as participants update expectations about inventory, shipping, sanctions, demand destruction, and policy response.

The phase statistics reinforce the same story. In the shock and escalation stage, average Brent reaches 106.32 with average daily Brent return of 4.56%, the strongest of any phase. In the peak crisis stage, the average price level remains even higher at 117.54, but the average daily return moderates. That means the market shifted from rapid repricing to consolidation at a higher plateau. Business users should interpret this as a transition from crisis recognition to crisis absorption.

For planning teams, the distinction is important. During initial repricing, the immediate question is how much more expensive barrels have become. During peak crisis consolidation, the key question changes to duration: how long will elevated prices persist, and should assumptions be reset in budgets, customer contracts, or margin forecasts? The dataset suggests the answer is yes, because elevated prices survive well beyond the first event burst.

Figure: 06 Phase Prices

Figure: 01 Price Series

7. Extreme Swings and Repricing Risk

The phase classified as Extreme swings captures a shift from elevated prices to highly unstable prices. In this segment, average Brent remains high at 119.42, but the average return turns negative and average volatility reaches the highest phase-level reading in the sample. The period therefore represents a market that is still expensive but no longer one-directional. Instead of pure escalation, it exhibits violent repricing, including some of the sharpest negative daily moves in the entire dataset.

The largest one-day Brent loss occurs on 05 Apr 2026, when Brent return falls -12.54%. WTI likewise records its worst daily performance on 05 Apr 2026, dropping -9.33%. These reversals matter because they expose an operational trap: organizations that respond to a shock only after prices spike may find themselves hedging at poor levels just before a corrective move. The presence of extreme negative days therefore amplifies the cost of delayed decision-making.

A second implication is that mark-to-market volatility becomes a management issue in its own right. Even if procurement volume is hedged, accounting results, collateral requirements, and internal risk appetite can still be stressed by large day-to-day swings. The dataset therefore supports the case for scenario planning, trigger-based decision rules, and dashboard thresholds that distinguish between high but stable prices and high plus unstable prices.

Figure: 09 Histogram

Figure: 03 Volatility

8. De-escalation and Residual Premium

By the de-escalation phase, average Brent declines to 108.10 and average WTI to 94.50. Returns turn negative on average, which signals a cooling process. Yet de-escalation does not imply a full return to baseline. Brent still ends the sample at \$106.0, far above its starting level of \$69.4. WTI ends at \$94.0, also materially above its initial price. The market therefore gives back some crisis premium but not all of it.

This is a critical business insight. Procurement teams often hope that a shock-driven spike will fully unwind, restoring the original planning environment. The sample warns against that assumption. Even after the event indicator turns off, residual geopolitical or structural premium may remain in the price level. That means organizations should not wait for a complete normalization before revising operating assumptions. Instead, they should recalibrate to a new equilibrium unless stronger evidence of reversal appears.

The de-escalation stage also illustrates why regime labels should not be confused with direction alone. A de-escalating market can still be expensive, volatile, and strategically relevant. In governance terms, this suggests that dashboards should preserve event-aware monitoring for some time after the visible shock fades, because latent market fragility can continue to influence spreads, volatility, and downside risk.

Figure: 07 Cumulative Returns

9. Event vs Normal Regime Comparison

The cleanest way to quantify impact is to compare event-tagged observations with normal observations. Event days carry an average Brent price of \$112.71, against \$82.16 on normal days. For WTI the gap is similarly large: \$102.43 versus \$74.29. This simple segmentation alone demonstrates a meaningful level shift in the market regime.

Returns tell a nuanced story. Average Brent return is 2.16% on event days versus -0.16% on normal days. Average WTI return shows a smaller difference, but the direction remains consistent with stronger upward pressure during event days. That means the event regime not only raised prices but also concentrated the strongest upside sessions. In commercial language, it increased both the cost level and the speed with which costs could change.

Volatility also rises under the event regime, with Brent volatility averaging 0.0474 compared with 0.0441 on normal days. WTI shows a similar pattern. For business users this combination of higher price level and higher volatility is the most difficult risk mix because it raises average spend while simultaneously weakening forecast confidence.

Figure: 05 Event Vs Normal Prices

10. Brent-WTI Relationship and Spread Dynamics

Brent and WTI remain tightly linked throughout the sample. The price correlation is 0.9894 and the return correlation is 0.9048. These are very high values and imply that both benchmarks were responding to the same broad macro and geopolitical forces. In other words, the crisis was transmitted across the oil complex rather than isolated to one benchmark.

At the same time, the relationship is not perfectly uniform. The average Brent-WTI spread is \$9.57, and it widens to \$20.20 on 10 Apr 2026. A widening spread is economically important because it signals that the shock premium embedded in Brent-linked barrels can exceed the premium in inland U.S.-linked crude. For globally exposed buyers or firms pricing off Brent, this means the benchmark selection itself affects risk outcomes.

The spread analysis therefore complements the simple price-level analysis. Two organizations may both say that oil prices rose sharply, but one exposed mainly to Brent can still face a steeper relative cost shock than one indexed more heavily to WTI. A good executive dashboard should therefore include both benchmark levels and the inter-benchmark spread, not merely one of them.

Figure: 04 Spread

Figure: 08 Scatter

11. Volatility, Risk Transmission, and Return Distribution

Volatility is the dataset's clearest proxy for uncertainty. Both Brent and WTI volatility lines rise substantially during the event window, with the most elevated readings appearing around the late-shock to early-correction period. This suggests that once the market accepted a higher price range, uncertainty shifted from direction to durability and magnitude. In practical terms, the question stopped being only whether prices would rise and became whether they would overshoot, reverse, or stabilize at a new plateau.

The return distribution confirms the asymmetry of crisis markets. There are several very large positive days and several outsized negative days, far beyond what would be expected in a quiet market. This combination tends to punish organizations with rigid operating rules or slow approval cycles, because the cost of waiting is high in both directions: delay can mean buying after a spike or failing to capitalize on a correction.

Risk transmission also appears stronger in prices than in the binary event flag itself. The event indicator correctly marks the regime, but the volatility series reveals that market stress persists even when a simple event/non-event framing becomes less informative. That is why mature risk dashboards use event tags as context but rely on continuous indicators such as volatility, spread, and cumulative performance for active monitoring.

Figure: 03 Volatility

Figure: 09 Histogram

12. Review of the SQL Analytical Design

The SQL file is well aligned with the questions a business analyst would ask of this dataset. It begins with data inspection and dimensional checks, then moves into ranking and threshold queries such as highest price day, lowest price day, and days above 100 dollars. It also evaluates best and worst return days, positive versus negative sessions, average volatility, and event-day versus normal-day comparisons. These are appropriate first-order analyses for an event-driven commodity dataset.

A particularly strong feature of the SQL design is the inclusion of narrative segmentation. The queries classify the time series into pre-crisis, shock and escalation, peak crisis, extreme swings, and de-escalation. This transforms a simple price table into a business storyline. It is easier for decision-makers to understand phase-based conclusions than to interpret a raw chronological list of numbers. The SQL also computes cumulative return and change-from-start measures, which are valuable because they frame the size of the move in intuitive terms.

From a governance perspective, the next improvement would be parameterization. Thresholds such as Brent above 100, volatility band cutoffs, and crisis phase dates are currently embedded in the script. Moving those into variables or a control table would improve maintainability, auditability, and adaptability if the same logic is reused for future events or broader historical datasets.

Phase	Days	Avg Brent	Avg WTI	Avg Brent Return	Avg Brent Volatility
Pre-crisis	7	71.04	65.63	1.33%	0.0372
Shock & escalation	11	106.32	97.55	4.56%	0.0493
Peak crisis	9	117.54	107.11	0.72%	0.0383
Extreme swings	4	119.42	105.33	-1.19%	0.0631
De-escalation	3	108.10	94.50	-3.65%	0.0602

13. Review of the Power BI Dashboard Design

The PBIX file contains one report page and sixteen visual containers. The mix includes a card visual, a slicer, multiple line charts, a clustered column chart, an area chart, a pie chart, a combined line-and-column chart, and several shape-based design elements. Structurally, this is a sensible composition for an executive dashboard because it supports KPI display, filtering, trend analysis, category comparison, and visual framing on a single page.

The dashboard appears designed to tell the same story embedded in the SQL: headline KPI, time-series movement, event segmentation, and comparative visuals. That is appropriate for a business audience because oil-market events need both a top-level summary and a sequential explanation. The presence of a slicer indicates some user interactivity, which is useful if executives want to isolate periods, metrics, or categories without asking analysts to rebuild the report.

The main design recommendation is to tighten the link between narrative and controls. If the dashboard is intended for active decision support, it should make phase changes, event onset, and spread widening unmistakable. Tooltips or annotation layers would also help. Even a strong one-page layout can become more decision-useful if it clearly answers: what changed, when did it change, how extreme was it, and what remains abnormal now?

Figure: 01 Price Series

Figure: 05 Event Vs Normal Prices

14. Business Implications and Management Actions

The analysis has direct implications for procurement, treasury, budgeting, and commercial strategy. For procurement teams, the event regime raises the probability that spot purchases become materially more expensive in a very short time. For treasury and hedging teams, the combination of higher price level and elevated volatility increases the value of pre-defined risk triggers, hedge bands, and exposure reporting. For budgeting teams, the sample shows why a single base-case oil assumption is insufficient during crisis windows; multiple scenarios are needed.

Commercially, organizations exposed to Brent-based pricing should pay special attention to the spread analysis. A widening Brent premium means that relying on generic 'oil price' commentary can understate actual cost pressure in Brent-linked contracts. Meanwhile, the persistence of elevated prices after de-escalation suggests that customer pricing, margin targets, and working capital assumptions may need adjustment even after the headline crisis appears to cool.

Operationally, management should treat the dashboard and SQL script as the nucleus of an ongoing monitoring system rather than a one-off exercise. Recommended next steps include adding threshold alerts, maintaining a daily refresh process, documenting the volatility methodology, and expanding the dataset with volume, inventory, freight, or refinery margin variables so that price moves can be interpreted alongside market fundamentals.

Figure: 04 Spread

15. Limitations and Opportunities for Enhancement

This report is analytically useful but rests on a deliberately compact dataset. The main limitation is sample size: 34 observations are enough to illustrate a crisis narrative, but not enough to infer long-run equilibrium relationships or robust predictive behavior. The event flag is also binary, which is useful for segmentation but too simple to capture event intensity or multiple overlapping catalysts.

Another limitation is documentation depth. The dataset contains volatility fields, but the methodology for calculating them is not embedded in the file itself. Likewise, the event tag does not explain the precise business meaning of the event or whether it denotes geopolitical escalation, supply disruption, sanctions risk, or another driver. Additional metadata would make the analysis stronger and more reusable.

The highest-value enhancement would be to extend the historical backfill and combine this time series with external drivers such as inventory changes, OPEC communication, freight rates, implied volatility, or currency movements. That would allow the current descriptive report to evolve into a richer explanatory and forecasting framework.

16. Conclusion

The supplied files together tell a coherent business story. A stable oil market baseline was disrupted by an event-driven shock that quickly pushed Brent and WTI sharply higher, widened the Brent premium, and lifted volatility. Brent peaked at \$127.6 while WTI reached \$112.5, and even after the market cooled, both benchmarks ended well above where they started. The event therefore produced both an immediate pricing shock and a durable change in the effective operating environment.

The SQL script and Power BI dashboard are aligned with this interpretation and already provide a solid reporting architecture. The next step is not to redesign the analytical concept, but to mature it: document assumptions, parameterize thresholds, extend historical context, and embed the model in a regular management process. If those improvements are implemented, the current project can serve as the foundation for a reliable commodity-risk reporting capability rather than just a one-time event summary.

In short, the evidence supports a clear managerial conclusion: the event regime materially increased oil price risk, affected Brent more severely in relative terms through spread widening, and left a residual premium even after the initial panic eased. Any business exposed to oil-linked costs should view such a pattern as a signal to improve both monitoring and response speed.
